**In a typical multiple-input and multiple-output (MIMO) radar scenario, the receive nodes transmit to a fusion center either samples of the target returns, or the results of matched filtering with the transmit waveforms. Based on the data it receives from multiple antennas, the fusion center formulates a matrix, referred to as the data matrix, which, via standard array processing schemes leads to target detection and parameter estimation. In this paper, it is shown that under certain conditions, the data matrix is low rank and thus can be recovered based on knowledge of a small subset of its entries via matrix completion (MC) techniques. Leveraging the low-rank property of the data matrix, we propose a new MIMO radar approach, termed, MIMO-MC radar, in which each receive node either performs matched filtering with a small number of randomly selected dictionary waveforms or obtains sub-Nyquist samples of the target returns at random sampling instants, and forwards the results to a fusion center. Based on the received samples, and with knowledge of the sampling scheme, the fusion center partially fills the data matrix and subsequently applies MC techniques to estimate the full matrix. MIMO-MC radars share the advantages of MIMO radars with compressive sensing, (MIMO-CS), i.e., high resolution with reduced amounts of data, but unlike MIMO-CS radars do not require grid discretization. The MIMO-MC radar concept is illustrated through a uniform linear array configuration, and its target estimation performance is demonstrated via simulations.**

## I. INTRODUCTION

Multiple-input and multiple-output (MIMO) radar systems have received considerable attention in recent years due to their superior resolution [3–5]. MIMO radars using compressed sensing (MIMO-CS) maintain the MIMO radars advantages, while significantly reducing the required measurements per receive antenna [6, 7]. In MIMO-CS radars, the target parameters are estimated by exploiting the sparsity of targets in the angle, Doppler, and range space, referred to as the target space; the target space is discretized into a fine grid, based on which a sparsifying matrix is constructed, and the target is estimated via sparse signal recovery techniques, such as the Dantzig selector [7]. However, the performance of CS-based MIMO radars degrades when the targets fall between grid points, a case also known as basis mismatch [8, 9].

In this paper, a novel approach to lower-complexity, higher-resolution radars is proposed, termed MIMO-MC radars, which stands for MIMO radars using matrix completion (MC). MIMO-MC radars achieve the advantages of MIMO-CS radars without requiring grid discretization. Matrix completion is of interest in cases in which we are constrained to observe only a subset of the entries of an  $n_1 \times n_2$  matrix because the cost of collecting all entries of a high dimensional matrix is high. If a matrix is low rank and satisfies certain conditions [10], it can be recovered exactly based on observations of a small number of its randomly selected entries. There are several MC techniques in the literature [10–16]. For example, in [10–13], recovery can be performed by solving a nuclear norm optimization problem, which basically finds the matrix with the smallest nuclear norm out of all possible matrices that fit the observed entries. Other matrix completion techniques are based on nonconvex optimization using matrix manifolds, such as Grassmann manifold [14, 15] and Riemann manifolds [16].

In a typical MIMO radar scenario [5], transmit nodes transmit orthogonal waveforms, while each receive node samples the target returns or performs matched filtering with the known set of transmit waveforms, and forwards the results to the fusion center. Based on the data it receives from multiple antennas, the fusion center formulates a matrix, referred to as the data matrix, which, in conjunction with standard array processing schemes, such as multiple signal classification (MUSIC) [17], leads to target detection and estimation. In this paper, we show that under certain conditions, the data matrix at the fusion center is low rank, which means that it can be recovered based on knowledge of a small subset of its entries via matrix completion techniques. Leveraging the low-rank property of that matrix, we propose MIMO-MC radars, in which, each receive antenna either performs matched filtering with a small number of dictionary waveforms, or obtains sub-Nyquist samples of the received signal and forwards the results to a fusion center. Based on the samples forwarded by all receive nodes, and with knowledge of the sampling scheme, the fusion center

applies MC to estimate the full matrix. Although the proposed ideas apply to arbitrary transmit and receive array configurations, in which the antennas are not physically connected, in this paper we illustrate the idea through a uniform linear array configuration. The properties and performance of the proposed scheme are demonstrated via simulations. Compared to MIMO-CS radars, MIMO-MC radars have the same advantage in terms of reduction of samples needed for accurate estimation, while they avoid the basis mismatch issue.

#### A. Relation to Prior Work

Array signal processing with MC has been studied in [18, 19]. To the best of our knowledge, MC has not been exploited for target estimation in colocated MIMO radars. Our paper is related to the ideas in [19] in the sense that MC is applied to the received data matrix formed by an array. However, due to the unique structure of the received signal in the MIMO radar scenario, the problem formulation and treatment is different than that of [19].

The paper is organized as follows. Background on noisy MC and colocated MIMO radars is provided in Section II. The proposed MIMO-MC radar approach is presented in Section III. Simulations results are given in Section IV. Finally, Section V provides some concluding remarks.

#### B. Notation

Lower-case and upper-case letters in bold denote vectors and matrices, respectively. Superscripts  $(\cdot)^H$  and  $(\cdot)^T$  denote Hermitian transpose and transpose, respectively.  $\mathbf{0}_{L \times M}$  and  $\mathbf{1}_{L \times M}$  denote an  $L \times M$  matrix with all 0 and all 1 entries, respectively.  $\mathbf{I}_M$  represents an identity matrix of size  $M$ .  $\otimes$  denotes the Kronecker tensor product.  $\|\mathbf{X}\|_*$  is the nuclear norm, i.e., sum of the singular values;  $\|\mathbf{X}\|$  is the operator norm;  $\|\mathbf{X}\|_F$  is the Frobenius norm;  $\mathbf{X}^*$  denotes the adjoint of  $\mathbf{X}$ .

## II. PRELIMINARIES

### A. Matrix Completion

In this section, we provide a brief overview of the problem of recovering a rank- $r$  matrix  $\mathbf{M} \in \mathbb{C}^{n_1 \times n_2}$  based on partial knowledge of its entries using the method of [10–13].

Let us define the observation operation  $\mathbf{Y} = \mathcal{P}_\Omega(\mathbf{M})$  as

$$[\mathbf{Y}]_{ij} = \begin{cases} [\mathbf{M}]_{ij}, & (i, j) \in \Omega \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

where  $\Omega$  is the set of indices of observed entries with cardinality  $m$ . According to [11], when  $\mathbf{M}$  is low rank and meets certain conditions, see (A0) and (A1), later in this section,  $\mathbf{M}$  can be estimated by solving a nuclear norm optimization problem

$$\begin{aligned} \min \quad & \|\mathbf{X}\|_* \\ \text{s.t.} \quad & \mathcal{P}_\Omega(\mathbf{X}) = \mathcal{P}_\Omega(\mathbf{M}) \end{aligned} \quad (2)$$

where  $\|\cdot\|_*$  denotes the nuclear norm, i.e., the sum of singular values of  $\mathbf{X}$ .

In practice, the observations are typically corrupted by noise, i.e.,  $[\mathbf{Y}]_{ij} = [\mathbf{M}]_{ij} + [\mathbf{E}]_{ij}$ ,  $(i, j) \in \Omega$ , where  $[\mathbf{E}]_{ij}$  represents noise. In that case, it holds that  $\mathcal{P}_\Omega(\mathbf{Y}) = \mathcal{P}_\Omega(\mathbf{M}) + \mathcal{P}_\Omega(\mathbf{E})$ , and the completion of  $\mathbf{M}$  is done by solving the following optimization problem [12]

$$\begin{aligned} \min \quad & \|\mathbf{X}\|_* \\ \text{s.t.} \quad & \|\mathcal{P}_\Omega(\mathbf{X} - \mathbf{Y})\|_F \leq \delta. \end{aligned} \quad (3)$$

Assuming that the noise is zero-mean, white,  $\delta > 0$  is a parameter related to the noise variance  $\sigma^2$  as  $\delta^2 = (m + \sqrt{8m})\sigma^2$  [12].

The conditions for successful MC involve the notion of incoherence, which is defined next [10].

**DEFINITION 1** Let  $U$  be a subspace of  $\mathbb{C}^{n_1}$  of dimension  $r$  that is spanned by the set of orthogonal vectors  $\{\mathbf{u}_i \in \mathbb{C}^{n_1}\}_{i=1, \dots, r}$ ,  $P_U$  the orthogonal projection onto  $U$ , i.e.,  $P_U = \sum_{1 \leq i \leq r} \mathbf{u}_i \mathbf{u}_i^H$ , and  $\mathbf{e}_i$  the standard basis vector whose  $i$ th element is 1. The coherence of  $U$  is defined as

$$\mu(U) = \frac{n_1}{r} \max_{1 \leq i \leq n_1} \|P_U \mathbf{e}_i\|^2 \in \left[1, \frac{n_1}{r}\right]. \quad (4)$$

Let the compact singular value decomposition (SVD) of  $\mathbf{M}$  be  $\mathbf{M} = \sum_{k=1}^r \rho_k \mathbf{u}_k \mathbf{v}_k^H$ , where  $\rho_k$ ,  $k = 1, \dots, r$  are the singular values, and  $\mathbf{u}_k$  and  $\mathbf{v}_k$  the corresponding left and right singular vectors, respectively. Let  $U, V$  be the subspaces spanned by  $\mathbf{u}_k$  and  $\mathbf{v}_k$ , respectively. Matrix  $\mathbf{M}$  has coherence with parameters  $\mu_0$  and  $\mu_1$  if

(A0)  $(\mu(U), \mu(V)) \leq \mu_0$  for some positive  $\mu_0$ .

(A1) The maximum element of the  $n_1 \times n_2$  matrix  $\sum_{1 \leq i \leq r} \mathbf{u}_i \mathbf{v}_i^H$  is bounded by  $\mu_1 \sqrt{r/(n_1 n_2)}$  in absolute value, for some positive  $\mu_1$ .

In fact, it was shown in [10] that if (A0) holds, then (A1) also holds with  $\mu_1 \leq \mu_0 \sqrt{r}$ .

Now, suppose that matrix  $\mathbf{M} \in \mathbb{C}^{n_1 \times n_2}$  satisfies (A0) and (A1). The following lemma gives a probabilistic bound for the number of entries,  $m$ , needed to estimate  $\mathbf{M}$ .

**THEOREM 1** [10] *Suppose that we observe  $m$  entries of the rank- $r$  matrix  $\mathbf{M} \in \mathbb{C}^{n_1 \times n_2}$ , with matrix coordinates sampled uniformly at random. Let  $n = \max\{n_1, n_2\}$ . There exist constants  $C$  and  $c$  such that if*

$$m \geq C \max \left\{ \mu_1^2, \mu_0^{1/2} \mu_1, \mu_0 n^{1/4} \right\} nr \beta \log n$$

for some  $\beta > 2$ , the minimizer to the program of (2) is unique and equal to  $\mathbf{M}$  with probability at least  $1 - cn^{-\beta}$ .

For  $r \leq \mu_0^{-1} n^{1/5}$ , the bound can be improved to

$$m \geq C \mu_0 n^{6/5} r \beta \log n$$

without affecting the probability of success.

Theorem 1 implies that the lower the coherence parameter  $\mu_0$ , the fewer entries of  $\mathbf{M}$  are required to estimate  $\mathbf{M}$ . The smallest possible value for  $\mu_0$  is 1.

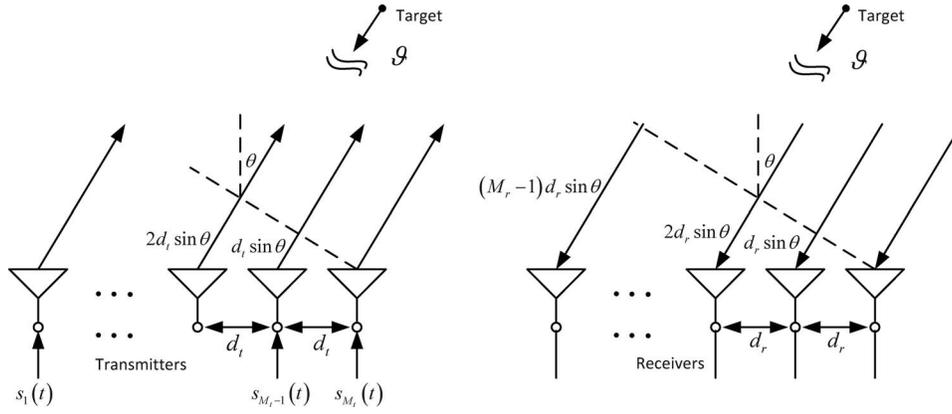

Fig. 1. Colocated MIMO radar system under ULA model. There are  $M_t$  transmit antennas and  $M_r$  receive antennas. Target is in direction  $\theta$  and moving with speed  $\vartheta$ .

Further, [12] establishes that, when the observations are corrupted with white zero-mean Gaussian noise with variance  $\sigma^2$ , the recovery error corresponding to the solution of (3) is bounded as

$$\|\mathbf{M} - \hat{\mathbf{M}}\|_F \leq 4\sqrt{\frac{1}{p}(2+p)\min(n_1, n_2)\delta} + 2\delta, \quad (5)$$

where  $p = \frac{m}{n_1 n_2}$  is the fraction of observed entries, and  $\delta^2 = (m + \sqrt{8m})\sigma^2$ .

## B. Colocated MIMO Radars

Let us consider a MIMO pulse radar system that employs colocated transmit and receive antennas, as shown in Fig. 1. We use  $M_t$  and  $M_r$  to denote the numbers of transmit and receive antennas, respectively. Although our results can be extended to an arbitrary antenna configuration, we illustrate the ideas for uniform linear arrays (ULAs). The interelement spacing in the transmit and receive arrays is denoted by  $d_t$  and  $d_r$ , respectively. The pulse duration is  $T_p$ , and the pulse repetition interval is  $T_{PRI}$ . The waveform of the  $i$ th transmit antenna is  $s_i(\tau) = \sqrt{\frac{E}{M_t}}\phi_i(\tau)$ , where  $E$  is the total energy for all the transmit antennas, and  $\phi_i(\tau)$ ,  $i = 1, \dots, M_t$  are orthonormal. The waveforms are transmitted over a carrier with wavelength  $\lambda$ . Let us consider a scenario with  $K$  point targets in the far field at angles  $\theta_k$ ,  $k = 1, \dots, K$ , each moving with speed  $\vartheta_k$ .

The following assumptions are made:

- 1) The transmit waveforms are narrowband, i.e.,  $\frac{1}{T_p} \ll \frac{c}{\lambda}$ , where  $c$  is the speed of light.
- 2) The target reflection coefficients  $\{\beta_k\}$ ,  $k = 1, \dots, K$  are complex and remain constant during a number of pulses,  $Q$ . Also, all parameters related to the array configuration remain constant during the  $Q$  pulses.
- 3) The delay spread in the receive signals is smaller than the temporal support of pulse  $T_p$ .
- 4) The Doppler spread of the receive signals is much smaller than the bandwidth of the pulse, i.e.,  $\frac{2\vartheta}{\lambda} \ll \frac{1}{T_p}$ .

Under the narrowband transmit waveform assumption, the delay spread in the baseband signals can be ignored. For slowly moving targets, the Doppler shift within a pulse can be ignored, while the Doppler changes from pulse to pulse. Thus, if we express time as  $t = qT_{PRI} + \tau$ , where  $q$  is the pulse index (or slow time) and  $\tau \in [0, T_p]$  is the time within a pulse (or fast time), the Doppler shift will depend on  $q$  only, and the received signal at the  $l$ th receive antenna can be approximated as [5]

$$\begin{aligned} x_l &\left(qT_{PRI} + \tau + \frac{2d}{c}\right) \\ &\approx \sum_{k=1}^K \beta_k e^{j\frac{2\pi}{\lambda}(2\vartheta_k(q-1)T_{PRI} + (l-1)d_r \sin(\theta_k))} \mathbf{a}^T(\theta_k) \mathbf{s}(\tau) \\ &\quad + w_l \left(qT_{PRI} + \tau + \frac{2d}{c}\right), \end{aligned} \quad (6)$$

where  $d$  is the distance of the range bin of interest,  $w_l$  contains both interference and noise,

$$\mathbf{a}(\theta_k) = \left[1, e^{j\frac{2\pi}{\lambda}d_t \sin(\theta_k)}, \dots, e^{j\frac{2\pi}{\lambda}(M_t-1)d_t \sin(\theta_k)}\right]^T, \quad (7)$$

and  $\mathbf{s}(\tau) = [s_1(\tau), \dots, s_{M_t}(\tau)]^T$ . For convenience, the signal parameters are summarized in Table I.

At the  $l$ th receive node, for  $(l = 1, \dots, M_r)$ , a matched filter bank [5] is used to extract the returns due to each transmit antenna [5] (see Fig. 2a). Consider a filter bank composed of  $M_t$  filters, corresponding to the  $M_t$  orthogonal transmit waveforms. The receive node performs  $M_t$  correlation operations and the maximum of each matched filter is forwarded to the fusion center. At the fusion center, the received signal due to the  $i$ th matched filter of the  $l$ th receive node, during the  $q$ th pulse, can be expressed in equation (8)

$$\begin{aligned} x_q(l, i) &= \sum_{k=1}^K \beta_k e^{j\frac{2\pi}{\lambda}(2\vartheta_k(q-1)T_{PRI} + (l-1)d_r \sin(\theta_k) + (i-1)d_t \sin(\theta_k))} \\ &\quad + w_q(l, i) \end{aligned} \quad (8)$$

for  $l = 1, \dots, M_r$ ,  $i = 1, \dots, M_t$ , and  $q = 1, \dots, Q$ , where  $w_q(l, i)$  is the corresponding interference plus white noise.

TABLE I  
List of Parameters Used in the Signal Model

$d_t$	Spacing between the transmit antennas
$d_r$	Spacing between the receive antennas
$M_t$	Number of transmit antennas
$M_r$	Number of receive antennas
$Q$	Number of pulses in a coherent processing interval
$T_{PRI}$	Radar pulse repetition interval
$q$	Index of radar pulse (slow time)
$\tau$	Time in one pulse (fast time)
$\vartheta$	Speed of target
$\phi_m$	Baseband waveform
$d$	Distance of range bin of interest
$c$	Speed of light
$\theta$	Direction of arrival of the target
$\beta$	Target reflect coefficient
$\lambda$	Wavelength of carrier signal
$w_l$	Interference and white noise in the $l$ th antenna
$T_p$	Duration of one pulse
$T_s$	Nyquist sampling period

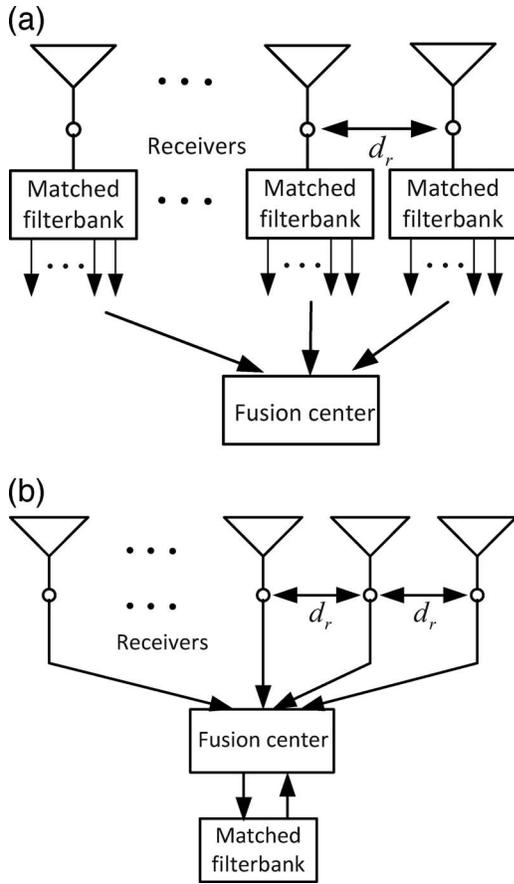

Fig. 2. Two sampling schemes in colocated MIMO radar system.  
(a) Sampling scheme I. (b) Sampling scheme II.

Based on the data from all receive antennas, the fusion center can construct a matrix  $\mathbf{X}_q^{MF}$ , of size  $M_r \times M_t$ , whose  $(l, i)$  element equals  $x_q(l, i)$ . That matrix can be expressed as

$$\mathbf{X}_q^{MF} = \underbrace{\mathbf{B}\mathbf{\Sigma}\mathbf{D}_q\mathbf{A}^T}_{\mathbf{Z}_q^{MF}} + \mathbf{W}_q^{MF}, \quad (9)$$

where  $\mathbf{W}_q^{MF}$  is the filtered noise;  $\mathbf{D}_q = \text{diag}(\mathbf{d}_q)$ , with  $\mathbf{d}_q = \left[ e^{j\frac{2\pi}{\lambda}2\vartheta_1(q-1)T_{PRI}}, \dots, e^{j\frac{2\pi}{\lambda}2\vartheta_K(q-1)T_{PRI}} \right]^T$ ;  $\mathbf{\Sigma} = \text{diag}([\beta_1, \dots, \beta_K])$ ;  $\mathbf{A}$  is the  $M_t \times K$  transmit steering matrix, defined as  $\mathbf{A} = [\mathbf{a}(\theta_1), \dots, \mathbf{a}(\theta_K)]$ ; and  $\mathbf{B}$  is the  $M_r \times K$  dimensional receive steering matrix, defined in a similar fashion based on the receive steering vectors

$$\mathbf{b}(\theta_k) = \left[ 1, e^{j\frac{2\pi}{\lambda}d_r \sin(\theta_k)}, \dots, e^{j\frac{2\pi}{\lambda}(M_r-1)d_r \sin(\theta_k)} \right]^T. \quad (10)$$

### C. MIMO Radars without Matched Filtering

In this scenario, each receive antenna performs Nyquist sampling to obtain  $N$  samples from the target returns and forwards them to the fusion center (see Fig. 2b). If the data forwarded by the  $l$ th antenna ( $l = 1, \dots, M_r$ ) are inserted in the  $l$ th row of an  $M_r \times N$  matrix,  $\mathbf{X}_q$ , then an equation similar to (9) holds, except that now the transmit waveforms also appear in the expression, i.e., [20]

$$\mathbf{X}_q = \underbrace{\mathbf{B}\mathbf{\Sigma}\mathbf{D}_q\mathbf{A}^T}_{\mathbf{Z}_q} \mathbf{S} + \mathbf{W}_q, \quad (11)$$

where  $\mathbf{S} = [\mathbf{s}(0T_s), \dots, \mathbf{s}((N-1)T_s)] \in \mathbb{C}^{M_t \times N}$ .

### III. THE PROPOSED MIMO-MC RADAR APPROACH

Looking at (9), if  $M_t > K$  and  $M_r > K$ , both matrices  $\mathbf{\Sigma}$  and  $\mathbf{D}_q$  are rank- $K$ . Thus, the rank of the noise-free matrix  $\mathbf{Z}_q^{MF} \in \mathbb{C}^{M_r \times M_t}$  is  $K$ , which implies that matrix  $\mathbf{Z}_q^{MF}$  is low rank if both  $M_t$  and  $M_r$  are much larger than  $K$ .

Similarly, looking at (11), both matrices  $\mathbf{\Sigma}$  and  $\mathbf{D}_q$  are rank- $K$ . The rank of matrix  $\mathbf{S}$  is  $\min\{M_t, N\}$ . Let us assume that  $N > M_t$ . For  $M_t > K$ , the rank of the noise-free data matrix  $\mathbf{Z}_q \in \mathbb{C}^{M_r \times N}$  is  $K$ . In other words, for  $M_r \gg K$ , the data matrix  $\mathbf{Z}_q$  is low rank.

Therefore, in both sampling schemes, assuming that the conditions (A0) and (A1) are satisfied, the fusion center matrix can be recovered from a small number of its entries. The estimated matrices corresponding to several pulses can be used to estimate the target parameters via, e.g., MUSIC [17].

In the following, we leverage the low-rank property of the data matrices at the fusion center to propose a new MIMO radar approach. Because both  $\mathbf{Z}_q$  and  $\mathbf{Z}_q^{MF}$  are formulated based on different sampling schemes at the receive nodes, we will study two cases, namely, sampling scheme I, which gives rise to  $\mathbf{Z}_q^{MF}$ , and sampling scheme II, which gives rise to  $\mathbf{Z}_q$ .

#### A. MIMO-MC with Sampling Scheme I

Suppose that the  $l$ th receive node uses a random matched filter bank, as shown in Fig. 3, in which a random switch unit is used to turn on and off each matched filter. Suppose that  $L_1$  matched filters are selected at random out of the  $M_t$  available filters, according to the output of a random number generator, returning  $L_1$  integers in  $[0, M_t - 1]$  based on the seed  $s_l$ . Let  $\mathcal{J}^l$  denote the set of

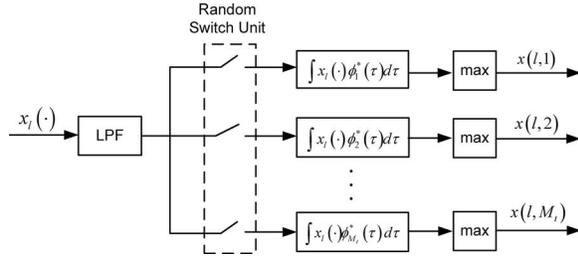

Fig. 3. Structure of random matched filter bank.

indices of the selected filters. The same random generator algorithm is also available to the fusion center. The  $l$ th receive antenna forwards the  $L_1$  samples along with the seed  $s_l$  to the fusion center. Based on the seed  $s_l$ , the fusion center generates the indices  $\mathcal{J}^l$ . Then, it places the  $j$ th sample of the  $l$ th antenna in the  $M_r \times M_t$  matrix  $\mathbf{Z}_q^{MF}$  at location  $(l, \mathcal{J}^l(j))$ . In total,  $L_1 M_t$  entries of the matrix are filled. The fusion center declares the rest of the entries as missing, and assuming that  $\mathbf{Z}_q^{MF}$  meets (A0) and (A1), applies MC techniques to estimate the full data matrix.

Because the samples forwarded by the receive nodes are obtained in a random sampling fashion, the filled entries of  $\mathbf{Z}_q^{MF}$  will correspond to a uniformly random sampling of  $\mathbf{Z}_q^{MF}$ . In order to show that  $\mathbf{Z}_q^{MF}$  indeed satisfies (A0), and as a result (A1), we need to show that the maximum coherence of the spaces spanned by the left and right singular vectors of  $\mathbf{Z}_q^{MF}$  is bounded by a number,  $\mu_0$ . The smaller that number, the fewer samples of  $\mathbf{Z}_q^{MF}$  will be required for estimating the matrix. The theoretical analysis is pursued separately in [21]. Here, we confirm the applicability of MC techniques via simulations.

We consider a scenario with  $K = 2$  point targets. The direction of arrival (DOA) of the first target  $\theta_1$  is taken to be uniformly distributed in  $[-90^\circ, 90^\circ]$ , while the DOA of the second target is taken to be  $\theta_2 = \theta_1 + \Delta\theta$ . The target speeds are taken to be uniformly distributed in  $[0, 500]$  m/s, and the target reflectivities  $\beta_k$  are taken to be zero-mean Gaussian. Both the transmit and receive arrays follow the ULA model with  $d_t = d_r = \frac{\lambda}{2}$ . The carrier frequency is taken as  $f = 1 \times 10^9$  Hz.

The left and right singular vectors of  $\mathbf{Z}_q^{MF}$  were computed for 500 independent realizations of  $\theta_1$  and target speeds. Among all the runs, the probability that  $\max(\mu(U), \mu(V)) > \mu_0$  is shown in Fig. 4a for  $\Delta\theta = 5^\circ$  and different values of  $M_r, M_t$ . One can see from the figure that in all cases, the probability that the coherence is bounded by a number less than 2 is very high, while the bound gets tighter as the number of receive or transmit antennas increases. On average, over all independent realizations, the value of  $\max(\mu(U), \mu(V))$  corresponding to different number of receive and transmit antennas and fixed  $\Delta\theta$  appears to decrease as the number of transmit and receive antennas increases (see Fig. 4b). Also, the maximum appears to decrease as  $\Delta\theta$  increases, reaching 1 for large  $\Delta\theta$  (see Fig. 4c). The rate at which the maximum reaches 1 increases as the number of antennas increases.

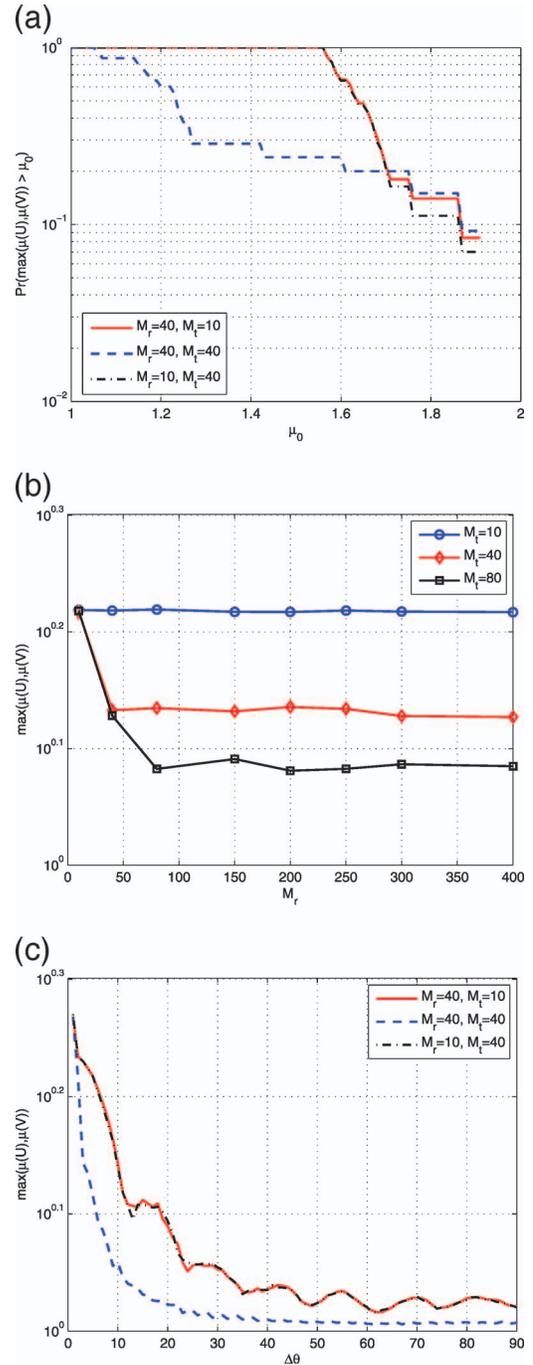

Fig. 4. Scheme I,  $K = 2$  targets. (a) Probability of  $\Pr(\max(\mu(U), \mu(V)) > \mu_0)$  of  $\mathbf{Z}_q^{MF}$  for  $\Delta\theta = 5^\circ$ . (b) Average  $\max(\mu(U), \mu(V))$  of  $\mathbf{Z}_q^{MF}$  as function of number of transmit and receive antennas, and for  $\Delta\theta = 5^\circ$ . (c) Average  $\max(\mu(U), \mu(V))$  of  $\mathbf{Z}_q^{MF}$  as function of DOA separation.

It is interesting to see what happens at the limit  $\Delta\theta = 0$ , i.e., when the two targets are on a line in the angle plane. Computing the coherence based on the assumption of rank-2, i.e., using two eigenvectors, the coherence shown in Fig. 5 appears unbounded as  $M_r$  changes. However, in this case, the true rank of  $\mathbf{Z}_q^{MF}$  is 1, and  $\mathbf{Z}_q^{MF}$  has the best possible coherence. Indeed, as it is shown in the Appendix A, for a rank-1  $\mathbf{Z}_q^{MF}$ , it holds that  $\mu_0 =$

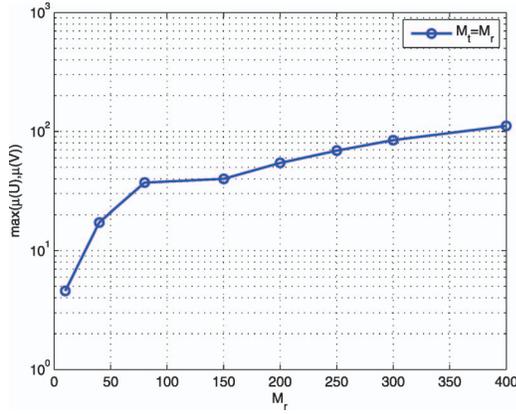

Fig. 5. Scheme I,  $K = 2$  targets. Max  $(\mu(U), \mu(V))$  in terms of  $M_r$  for  $\Delta\theta = 0^\circ$ ,  $M_t = M_r$ .

$\mu_1 = 1$ . Consequently, according to Theorem 1, the required number of entries to estimate  $\mathbf{Z}_q^{MF}$  is minimal. This explains why in Fig. 9 (discussed further in Section IV) the relative recovery error of  $\mathbf{Z}_q^{MF}$  goes to the reciprocal of signal-to-noise ratio (SNR) faster when the two targets have the same DOA. Of course, in this case, the two targets with the same DOA appear as one, and cannot be separated in the angle space unless other parameters, e.g., speed or range, are used. For multiple targets, i.e., for  $K \geq 3$ , if there are  $n$  ( $n < K$ ) targets with the same DOA, the rank of  $\mathbf{Z}_q^{MF}$  is  $K - n$ , which yields a low coherence condition because these  $K - n$  DOAs are separated.

### B. MIMO-MC with Sampling Scheme II

Suppose that the Nyquist rate samples of signals at the receive nodes correspond to sampling times  $t_i = iT_s$ ,  $i = 0, \dots, N - 1$  with  $N = T_p/T_s$ . Instead of the receive nodes sampling at the Nyquist rate, let the  $l$ th receive antenna sample at times  $\tau_j^l = jT_s$ ,  $j \in \mathcal{J}^l$ , where  $\mathcal{J}^l$  is the output of a random number generator, containing  $L_2$  integers in the interval  $[0, N - 1]$  according to a unique seed  $s_l$ . The  $l$ th receive antenna forwards the  $L_2$  samples along with the seed  $s_l$  to the fusion center. Under the assumption that the fusion center and the receive nodes use the same random number generator algorithm, the fusion center places the  $j$ th sample of the  $l$ th antenna in the  $M_r \times N$  matrix  $\mathbf{Z}_q$  at location  $(l, \mathcal{J}^l(j))$ , and declares the rest of the samples as missing.

Therefore, under conditions (A0) and (A1),  $\mathbf{Z}_q$  can be estimated based on  $m = L_2 M_r$  elements, for  $m$  sufficiently large.

The left singular vectors of  $\mathbf{Z}_q$  are the eigenvectors of  $\mathbf{Z}_q \mathbf{Z}_q^H = \mathbf{H} \mathbf{S} \mathbf{S}^H \mathbf{H}^H$ , where  $\mathbf{H} = \mathbf{B} \mathbf{\Sigma} \mathbf{D}_q \mathbf{A}^T$ . The right singular vectors of  $\mathbf{Z}_q$  are the eigenvectors of  $\mathbf{S}^H \mathbf{H}^H \mathbf{H} \mathbf{S}$ . Because the transmit waveforms are orthogonal, it holds that  $\mathbf{S} \mathbf{S}^H = \mathbf{I}$  [20]. Thus, the left singular vectors are only determined by matrix  $\mathbf{H}$ , while the right singular vectors are affected by both transmit waveforms and matrix  $\mathbf{H}$ .

Again, to check whether  $\mathbf{Z}_q$  satisfies the conditions for MC, we resort to simulations. In particular, we show that

the maximum coherence of  $\mathbf{Z}_q$  is bounded by a small positive number  $\mu_0$ . Assume there are  $K = 2$  targets. The DOA of the first target  $\theta_1$  is uniformly distributed in  $[-90^\circ, 90^\circ]$  and the DOA of the second target is set as  $\theta_1 + \Delta\theta$ . The corresponding speeds are uniformly distributed in  $[150, 450]$  m/s. The target reflectivities  $\beta_k$  are zero-mean, Gaussian distributed. The transmit waveforms are taken to be complex Gaussian orthogonal (G-Orth). The carrier frequency is  $f = 10^9$  Hz, resulting in  $\lambda = cf = 0.3$  m. The interspacing between transmit and receive antennas is set as  $d_t = d_r = \lambda/2$ , respectively.

The left and right singular vectors of  $\mathbf{Z}_q$  are computed for 500 independent realizations of  $\theta_1$  and target speeds. Among all the runs, the probability that the  $\max(\mu(U), \mu(V)) > \mu_0$  is shown in Fig. 6, for different values of  $M_t$ ,  $M_r$ ,  $\Delta\theta = 5^\circ$ , and  $N = 256$ . One can see from the figure that in all cases, the probability that the coherence is bounded by a number less than 7 is very high, while the bound gets tighter as the number of receive or transmit antennas increases. On average, over all independent realizations, the  $\max(\mu(U), \mu(V))$  corresponding to different values of  $M_t$ ,  $M_r$ , and a fixed  $\Delta\theta$  appears to increase with  $N$ , (see Fig. 6b), while the increase is not affected by the number of transmit and receive antennas. The average maximum does not appear to change as  $\Delta\theta$  increases, and this holds for various values of  $M_t$ ,  $N$  (see Fig. 6c).

Based on our simulations, the MC reconstruction depends on the waveform. In particular, the coherence bound is related to the power spectrum of each column of the waveform matrix (each column can be viewed as a waveform snapshot across the transmit antennas). Let  $\tilde{S}_i(\omega)$  denote the power spectrum of the  $i$ th column of  $\mathbf{S} \in \mathbb{C}^{M_t \times N}$ . If  $\tilde{S}_i(\omega)$  is similar for different  $i$ s, the MC recovery performance improves with increasing  $M_t$  (or equivalently, the coherence bound decreases) and does not depend on  $N$ ; otherwise, the performance worsens with increasing  $N$  (i.e., the coherence bound increases). When the  $\tilde{S}_i(\omega)$  has peaks at  $\omega$ s close to the  $\omega$ s corresponding to targets, the performance worsens. In Fig. 7, we show the maximum power spectra values corresponding to Hadamard and G-Orth waveforms for  $M_t = 10$  and  $N = 32$ . It can be seen in Fig. 7 that the maximum power spectrum values corresponding to the Hadamard waveform have strong peaks at certain  $\omega$ s, while those for the G-Orth waveforms fluctuate around a low value. Suppose that there are two targets at angles  $\theta_1 = 20^\circ$  and  $\theta_2 = 40^\circ$ , corresponding to  $\omega_1 = \frac{1}{2} \sin(\frac{\pi}{9})$  and  $\omega_2 = \frac{1}{2} \sin(\frac{2\pi}{9})$ , respectively. From Fig. 7, one can see that the targets fall under low power spectral values for both waveform cases. The corresponding MC recovery error, computed based on 50 independent runs is shown in Fig. 8a. One can see that the error is the same for both waveforms. As another case, suppose that the two targets are at angles  $0^\circ, 80^\circ$ , corresponding to  $\omega_1 = 0$ ,  $\omega_2 = \frac{1}{2} \sin(\frac{4\pi}{9})$ , respectively. Based on Fig. 7, one can see that  $\omega_1$  and  $\omega_2$  fall under high spectral peaks in the case of Hadamard waveforms. The corresponding MC recovery

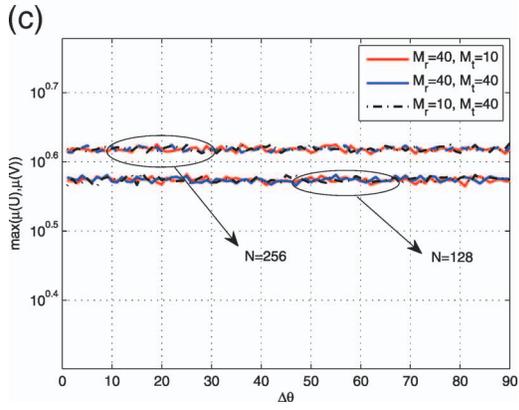

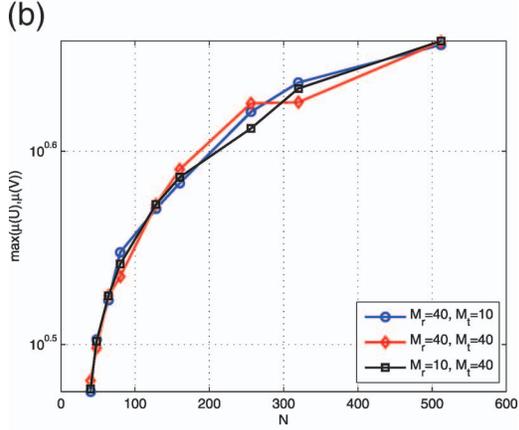

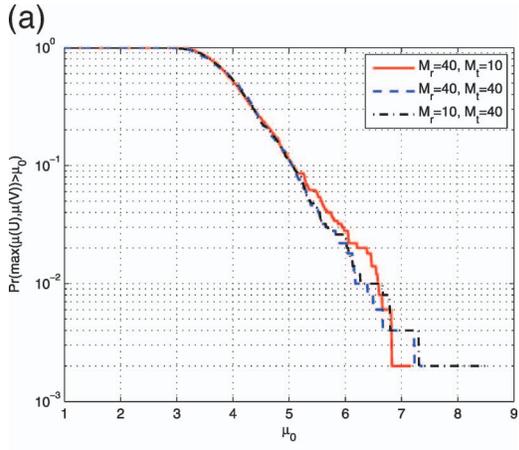

Fig. 6. Scheme II,  $K = 2$  targets, and G-Orth waveforms. (a) Probability  $\Pr(\max(\mu(U), \mu(V)) > \mu_0)$  of  $\mathbf{Z}_q$  for  $\Delta\theta = 5^\circ$  and  $N = 256$ . (b) Average  $\max(\mu(U), \mu(V))$  of  $\mathbf{Z}_q$  as function of  $N$ , for  $\Delta\theta = 5^\circ$  and different values of  $M_r, M_t$ . (c) Average  $\max(\mu(U), \mu(V))$  of  $\mathbf{Z}_q$  as function of  $\Delta\theta$ , for  $N = 128, 256$ , and different combinations of  $M_r, M_t$ .

error is shown in Fig. 8b, where one can see that Hadamard waveforms yield higher error.

### C. Discussion of MC in Sampling Schemes I and II

To apply the MC techniques in colocated MIMO radars, the data matrices  $\mathbf{Z}_q \in \mathbb{C}^{M_r \times N}$  and  $\mathbf{Z}_q^{MF} \in \mathbb{C}^{M_r \times M_t}$  need to be low rank and satisfy the coherence conditions with small  $\mu_i, i = 0, 1$ . We have already shown that the rank of the above two matrices equals the number of

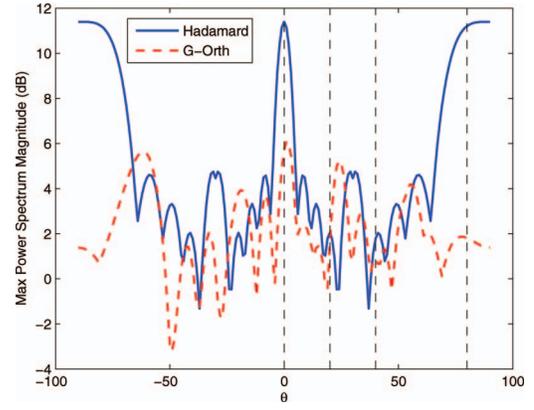

Fig. 7. Maximal power spectrum of orthogonal waveforms over  $N = 32$  snapshots for  $M_t = 10$ .

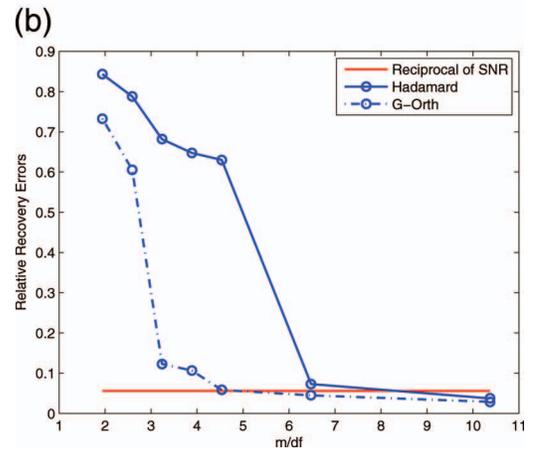

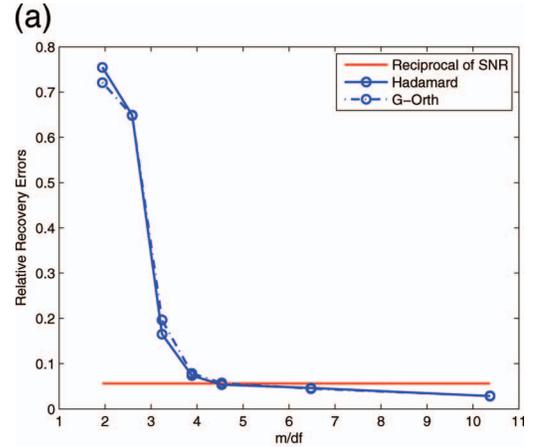

Fig. 8. Comparison of MC in terms of relative recovery errors with  $M_r = 128, M_t = 10, N = 32, \text{SNR} = 25 \text{ dB}$ . There are  $K = 2$  targets located at (a)  $20^\circ$  and  $40^\circ$ ; (b)  $0^\circ$  and  $80^\circ$ .

targets. In sampling scheme I, to ensure that matrix  $\mathbf{Z}_q^{MF}$  is low rank, both  $M_t$  and  $M_r$  need to be much larger than  $K$ , in other words, a large transmit as well as a large receive array are required. This, along with the fact that each receiver needs a filter bank, make scheme I more expensive in terms of hardware. However, the matched filtering operation improves the SNR in the received signals. Although in this paper we use the ULA model to

illustrate the idea of MIMO-MC radar, the idea can be extended to arbitrary antenna configurations. One possible scenario with a large number of antennas is a networked radar system [22, 23], in which the antennas are placed on the nodes of a network. In such scenarios, a large number of collocated or widely separated sensors could be deployed to collaboratively perform target detection.

In sampling scheme II, assuming that more samples ( $N$ ) are obtained than existing targets ( $K$ ),  $\mathbf{Z}_q$  will be low rank as long as there are more receive antennas than targets, i.e.,  $M_r \gg K$ . For this scheme, there is no condition on the number of transmit antennas  $M_t$  if G-Orth waveform is applied.

Based on Figs. 4 and 6, it appears that the average coherence bound  $\mu_0$  corresponding to  $\mathbf{Z}_q$  is larger than that of  $\mathbf{Z}_q^{MF}$ . This indicates that the coherence under scheme II is larger than that under scheme I, which means that for scheme II, more observations at the fusion center are required to recover the data matrix with missing entries.

#### D. Target Parameters Estimation with Subspace Methods

In this section, we describe the MUSIC-based method that will be applied to the estimated data matrices at the fusion center to yield target information. Let  $\hat{\mathbf{Z}}_q$  denote the estimated data matrix for sampling scheme II, during pulse  $q$ . Let us perform matched filtering on  $\hat{\mathbf{Z}}_q$  to obtain

$$\mathbf{Y}_q = \frac{1}{L} \hat{\mathbf{Z}}_q \tilde{\mathbf{S}}^H = \mathbf{B} \Sigma \mathbf{D}_q \mathbf{A}^T + \tilde{\mathbf{W}}_q, \quad (12)$$

where  $\tilde{\mathbf{W}}_q$  is noise whose distribution is a function of the additive noise and the nuclear norm minimization problem in (3). For sampling scheme I, a similar equation holds for the recovered matrix without further matched filtering.

Then, let us stack the matrices into vector  $\mathbf{y}_q = \text{vec}(\mathbf{Y}_q)$ , for sampling scheme II, or  $\mathbf{y}_q = \text{vec}(\hat{\mathbf{Z}}_q^{MF})$ , for sampling scheme I. Based on  $Q$  pulses, the following matrix can be formed:  $\mathbf{Y} = [\mathbf{y}_1, \dots, \mathbf{y}_Q] \in \mathbb{C}^{M_t M_r \times Q}$ , for which it holds that

$$\mathbf{Y} = \mathbf{V}(\theta) \tilde{\mathbf{X}} + \mathbf{W}, \quad (13)$$

where  $\tilde{\mathbf{X}} = [\tilde{\mathbf{x}}_1, \dots, \tilde{\mathbf{x}}_Q]$  is a  $K \times Q$  matrix containing target reflect coefficient and Doppler shift information;  $\tilde{\mathbf{x}}_q = [\tilde{x}_{1,q}, \dots, \tilde{x}_{K,q}]^T$  and  $\tilde{x}_{k,q} = \beta_k e^{j \frac{2\pi}{\lambda} 2\vartheta_k (q-1) T_{PRI}}$ ; and  $\mathbf{V}(\theta) = [\mathbf{v}(\theta_1), \dots, \mathbf{v}(\theta_K)]$  is a  $M_t M_r \times K$  matrix with columns

$$\mathbf{v}(\theta) = \mathbf{a}(\theta) \otimes \mathbf{b}(\theta) \quad (14)$$

and  $\mathbf{W} = [\text{vec}(\tilde{\mathbf{W}}_1), \dots, \text{vec}(\tilde{\mathbf{W}}_Q)]$ .

The sample covariance matrix can be obtained as

$$\hat{\mathbf{R}} = \frac{1}{Q} \sum_{n=1}^Q \mathbf{y}_n \mathbf{y}_n^H = \frac{1}{Q} \mathbf{Y} \mathbf{Y}^H. \quad (15)$$

According to [17], the pseudospectrum of the MUSIC estimator can be written as

$$P(\theta) = \frac{1}{\mathbf{v}^H(\theta) \mathbf{E}_n \mathbf{E}_n^H \mathbf{v}(\theta)}, \quad |\theta| < 90 \quad (16)$$

where  $\mathbf{E}_n$  is a matrix containing the eigenvectors of the noise subspace of  $\hat{\mathbf{R}}$ . The DOAs of target can be obtained by finding the peak locations of the pseudospectrum (16).

For joint DOA and speed estimation, we reshape  $\mathbf{Y}$  into  $\tilde{\mathbf{Y}} \in \mathbb{C}^{Q M_t \times M_r}$  and get

$$\tilde{\mathbf{Y}} = \mathbf{F} \Sigma [\mathbf{b}(\theta_1), \dots, \mathbf{b}(\theta_K)] + \mathbf{W}, \quad (17)$$

where  $\mathbf{F} = [\mathbf{d}(\vartheta_1) \otimes \mathbf{a}(\theta_1), \dots, \mathbf{d}(\vartheta_K) \otimes \mathbf{a}(\theta_K)]$ ,

$\mathbf{d}(\vartheta) = [1, e^{j \frac{2\pi}{\lambda} 2\vartheta T_{PRI}}, \dots, e^{j \frac{2\pi}{\lambda} 2\vartheta (Q-1) T_{PRI}}]^T$ . The sampled covariance matrix of the receive data signal can then be obtained as  $\hat{\mathbf{R}}_{\tilde{\mathbf{Y}}} = \frac{1}{M_r} \tilde{\mathbf{Y}} \tilde{\mathbf{Y}}^H$ , based on which DOA and speed joint estimation can be implemented using two-dimensional MUSIC. The pseudospectrum of two-dimensional MUSIC estimator is

$$P(\theta, \vartheta) = \frac{1}{[\mathbf{d}(\vartheta) \otimes \mathbf{a}(\theta)]^H \mathbf{E}_n \mathbf{E}_n^H [\mathbf{d}(\vartheta) \otimes \mathbf{a}(\theta)]} \quad (18)$$

where  $\mathbf{E}_n \in \mathbb{C}^{Q M_t \times (Q M_t - K)}$  is the matrix constructed by the eigenvectors corresponding to the noise-subspace of  $\hat{\mathbf{R}}_{\tilde{\mathbf{Y}}}$ .

#### IV. NUMERICAL RESULTS

In this section, we demonstrate the performance of the proposed approaches in terms of matrix recovery error and DOA resolution. We use ULAs for both transmitters and receivers. The internode distance for the transmit array is set to  $M_t \lambda / 2$ , while for the receive antennas, it is set as  $\lambda / 2$ . Therefore, the degrees of freedom of the MIMO radars is  $M_r M_t$  [24], i.e., a high resolution could be achieved with a small number of transmit and receive antennas. The carrier frequency is set to  $f = 1 \times 10^9$  Hz, which is a typical radar frequency. The noise introduced in both sampling schemes is white Gaussian with zero mean and variance  $\sigma^2$ . The data matrix recovery is done using the singular value thresholding (SVT) algorithm [25]. Nuclear norm optimization is a convex optimization problem. There are several algorithms available to solve this problem, such as templates for first-order conic solvers [26]. Here, we chose the SVT algorithm because it is a simple first-order method and is suitable for a large size problem with a low-rank solution. During every iteration of SVT, the storage space is minimal and computation cost is low.

We should note that in the SVT algorithm, the matrix rank, or equivalently, the number of targets, is not required to be known a priori. The only requirement is that the number of targets is much smaller than the number of transmit/receive antennas, so that the receive data matrix is low rank. To make sure the iteration sequences of SVT algorithm converge to the solution of the nuclear norm optimization problem, the thresholding parameter  $\tau$  should be large enough. In the simulation,  $\tau$  is chosen empirically and set to  $\tau = 5\zeta$ , where  $\zeta$  is the dimension of the low-rank matrix that needs to be recovered.

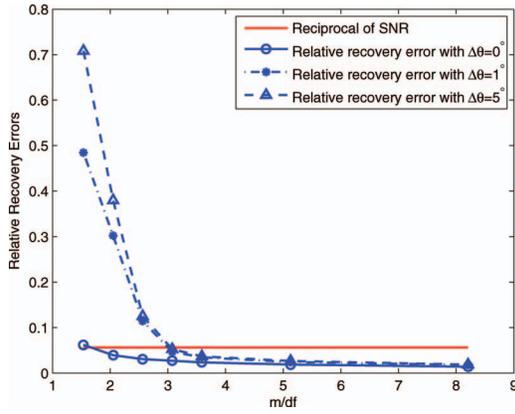

Fig. 9. Scheme I,  $K = 2$  targets: relative recovery error for  $\mathbf{Z}_q^{MF}$  under different values of DOA separation.  $M_r = M_t = 40$ .

#### A. Matrix Recovery Error under Noisy Observations

We consider a scenario with two targets. The first target DOA  $\theta_1$  is generated at random in  $[-90^\circ, 90^\circ]$ , and the second target DOA is taken as  $\theta_2 = \theta_1 + \Delta\theta$ . The target reflection coefficients are set as complex random, and the corresponding speeds are taken at random in  $[0, 500]$  m/s. The SNR at each receive antenna is set to 25 dB.

In the following, we compute the matrix recovery error as a function of the number of samples  $m$  per degrees of freedom df, i.e.,  $m/df$ , a quantity also used in [12]. A matrix of size  $n_1 \times n_2$  with rank  $r$  has  $r(n_1 + n_2 - r)$  degrees of freedom [10]. Let  $\phi_{\hat{\mathbf{Z}}}$  denote the relative matrix recovery error, defined as:

$$\phi_{\hat{\mathbf{Z}}} = \frac{\|\hat{\mathbf{Z}} - \mathbf{Z}\|_F}{\|\mathbf{Z}\|_F}, \quad (19)$$

where we use  $\mathbf{Z}$  to denote the data matrix in both sampling schemes and  $\hat{\mathbf{Z}}$  to denote the estimated data matrix.

Fig. 9 shows  $\phi_{\hat{\mathbf{Z}}}$  under sampling scheme I, versus the number of samples per degree of freedom for the same scenario as above. The number of transmit/receiver antennas is set as  $M_t = M_r = 40$ . It can be seen from Fig. 9 that when  $m/df$  increases from 2 to 4, or correspondingly, the matrix occupancy ratio increases from  $p_1 \approx 0.2$  to  $\approx 0.4$ , the relative error  $\phi_{\hat{\mathbf{Z}}}$  drops sharply to the reciprocal of the matched filter SNR level, i.e., a phase transition [14] occurs. It can be seen in Fig. 9 that, when the two targets have the same DOA, the relative recovery error is the smallest. This is because in that case the data matrix has the optimum coherence parameter, i.e.,  $\mu_0 = 1$ . As the DOA separation between the two target increases, the relative recovery error of the data matrix in the transition phase increases. In the subsequent DOA resolution simulations, we set the matrix occupancy ratio as  $p_1 = \frac{L_1 M_r}{M_r M_r} = 0.5$ , which corresponds to  $m/df \approx 5$ , to ensure that the relative recovery error has dropped to the reciprocal of the SNR level.

Fig. 10 shows the relative recovery errors,  $\phi_{\hat{\mathbf{Z}}}$ , for data matrix  $\mathbf{Z}_q$  (sampling scheme II), corresponding to Hadamard or G-Orth transmit waveforms, and the number

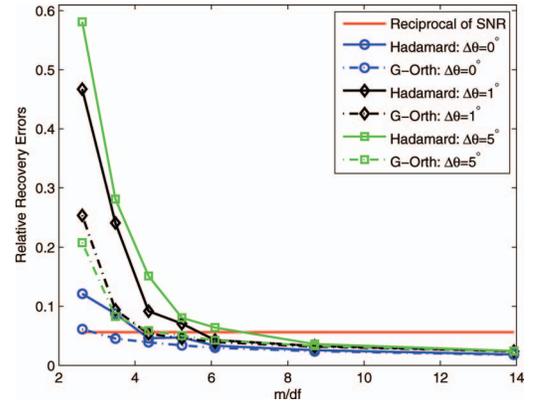

Fig. 10. Scheme II,  $K = 2$  targets: relative recovery errors for  $\hat{\mathbf{Z}}_q$  under Hadamard and G-Orth waveforms, and different values of  $\Delta\theta$ .  $M_r = M_t = 40, N = 256$ .

of Nyquist samples is taken to be  $N = 256$ . Different values of DOA separation for the two targets are considered, i.e.,  $\Delta\theta = 0^\circ, 1^\circ, 5^\circ$ , respectively.

The results are averaged over 100 independent angle and speed realizations; in each realization, the  $L_2$  samples are obtained at random among the  $N$  Nyquist samples at each receive antenna. The results of Fig. 10 indicate that, for the same  $\Delta\theta$ , as  $m/df$  increases, the relative recovery error,  $\phi_{\hat{\mathbf{Z}}}$ , under G-Orth waveforms (dash lines) reduces to the reciprocal of the SNR faster than under Hadamard waveforms (solid lines). A plausible reason for this is that under G-Orth waveforms, the average coherence parameter of  $\mathbf{Z}_q$  is smaller as compared with that under Hadamard waveforms. Under G-Orth waveforms, the error  $\phi_{\hat{\mathbf{Z}}}$  decreases as  $\Delta\theta$  increases. On the other hand, for Hadamard waveforms, the relative recovery error appears to increase with an increasing  $\Delta\theta$ , a behavior that diminishes in the region to the right of the point of phase transition. However, the behavior of the error at the left of the phase transition point is not of interest as the MC errors are pretty high and DOA estimation is simply not possible. At the right of the phase transition point, the observation noise dominates in the DOA estimation performance.

In both waveforms, the minimum error is achieved when  $\Delta\theta = 0^\circ$ , i.e., when the two targets have the same DOA, in which case, the rank of data matrix  $\mathbf{Z}_q$  is rank-1. The above observations suggest that the waveforms do affect performance, and optimal waveform design would be an interesting problem. The waveform selection problem could be formulated as an optimization problem under the orthogonal and narrow-band constraints. We plan to pursue this in our future work. Finally, it can be seen from Figs. 9 and 10 that in the noisy cases, as the matrix occupancy ratio increases, the relative recovery errors of the matrices decreases to the reciprocal of SNR.

#### B. DOA Resolution with MC

In this section, we study the probability that two DOAs will be resolved based on the proposed techniques. Two

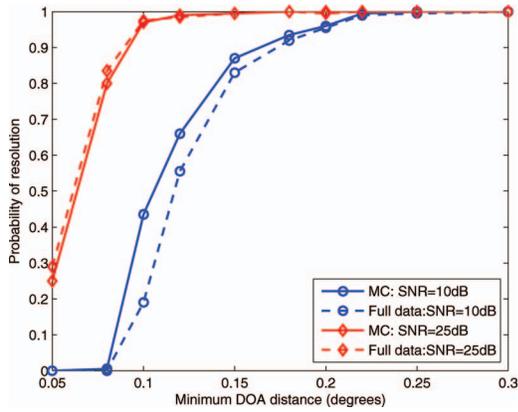

Fig. 11. Scheme I: DOA resolution. Parameter are set as  $M_r = M_t = 20$ ,  $p_1 = 0.5$ , and SNR = 10, 25 dB.

targets are generated at  $10^\circ$  and  $10^\circ + \Delta\theta$ , where

$$\Delta\theta = [0.05^\circ, 0.08^\circ, 0.1^\circ, 0.12^\circ, 0.15^\circ, 0.18^\circ, 0.2^\circ, 0.22^\circ, 0.25^\circ, 0.3^\circ].$$

The corresponding target speeds are set to 150 and 400 m/s. We set  $M_t = M_r = 20$  and  $Q = 5$ . The DOA information is obtained by finding the peak locations of the pseudospectrum (17). If the DOA estimates  $\hat{\theta}_i$ ,  $i = 1, 2$  satisfy  $|\theta_i - \hat{\theta}_i| \leq \varepsilon \Delta\theta$ ,  $\varepsilon = 0.1$ , we declare the estimation a success. The probability of DOA resolution is then defined as the fraction of successful events in 200 iterations. For comparison, we also plot the probability curves with full data matrix observations.

First, for scheme I,  $L_1 = 10$  matched filters are independently selected at random at each receive antenna, resulting in matrix occupancy ratio of  $p_1 = 0.5$ . The corresponding probability of DOA resolution is shown in Fig. 11. As expected, the probability of DOA resolution increase as the SNR increases. The performance of DOA resolution based on the full set of observations has similar behavior. When SNR = 25 dB, the performance of MC-based DOA estimation is close to that with the full data matrix. Interestingly, for SNR = 10 dB, the MC-based result is better than that corresponding to a full data matrix. Most likely, the MC acts like a low-rank approximation of  $\mathbf{Z}_q^{MF}$  and thus eliminates some of the noise.

The probabilities of DOA resolution of DOA estimates under scheme II, with G-Orth and Hadamard waveforms, are plotted in Figs. 12a and 12b, respectively. The parameters are set to  $N = 256$  and  $p_2 = 0.5$ , i.e., each receive antenna uniformly selects  $L_2 = 128$  samples at random to forward. Similarly, the simulation results show that under scheme II, the performance at SNR = 10 dB is slightly better than that with full data access. In addition, it can be seen that the performance with G-Orth waveforms is better than with Hadamard waveforms. This is because the average coherence of  $\mathbf{Z}_q$  under Hadamard waveforms is higher than that with G-Orth waveforms. As shown in Fig. 12, increasing the SNR from 10 dB to 25 dB can greatly improve the DOA estimation performance because it benefits both the MC and the performance of

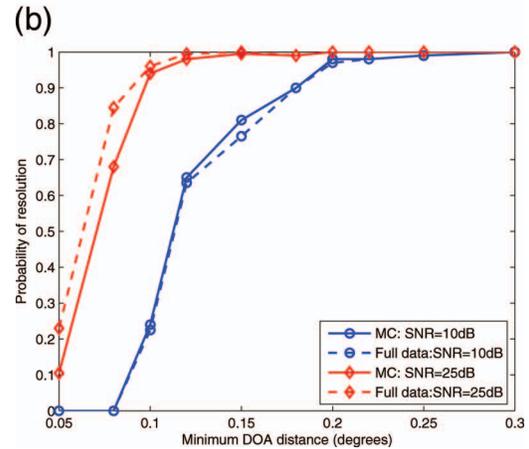

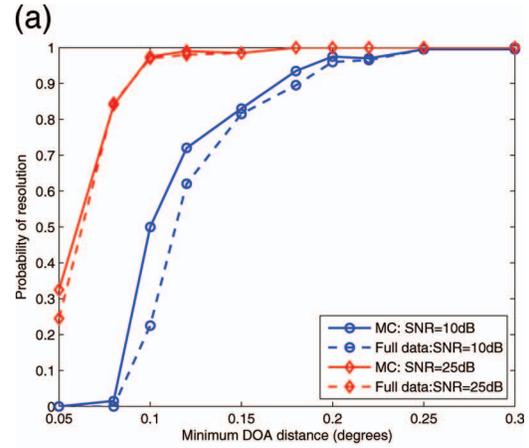

Fig. 12. Scheme II,  $K = 2$ ,  $M_r = M_t = 20$ ,  $N = 256$ ,  $p_2 = 0.5$ , SNR = 10, 25 dB. DOA resolution with (a) G-Orth waveforms and (b) Hadamard waveforms.

subspace-based DOA estimation method, i.e., MUSIC (see chap. 9 in [17]).

### C. Comparisons of Sampling Schemes I and II

Comparing the two sampling methods based on the above figures (see Figs. 11, 12a, 12b), we see that although the performance is the same, sampling scheme I uses fewer samples, i.e.,  $10 \times 20$  samples, as compared to sampling scheme II, which uses  $128 \times 20$  samples. To further elaborate on this observation, we compare the performance of the two sampling schemes when they both forward to the fusion center the same number of samples. The parameters are set to SNR = 25 dB,  $p_1 = p_2 = 0.5$  and  $M_t = N$ . Therefore, in both schemes, the number of samples forwarded by each receive antenna was the same. The number of transmit antenna was set as  $M_r = 40$  and 80, respectively. G-Orth transmit waveforms are used. Two targets are generated at random in  $[-90^\circ, 90^\circ]$  at two different DOA separations, i.e.,  $\Delta\theta = 5^\circ, 30^\circ$ . The results are averaged over 100 independent realizations; in each realization, the targets are independently generated at random, and the subsampling at each receive antenna is also independent between realizations. The relative recovery error comparison is plotted in Fig. 13.

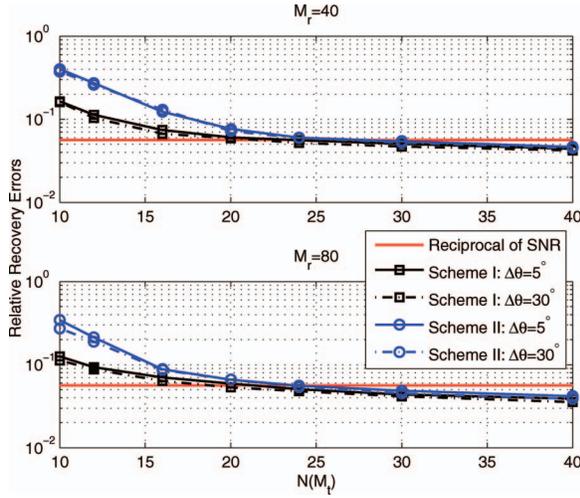

Fig. 13. Comparisons of relative recovery errors in terms of number of  $N(M_t)$  for  $M_r = 40, 80$ . The matrix occupancy ratio is set to  $p_1 = p_2 = 0.5$ . Two targets are generated at random in  $[-90^\circ, 90^\circ]$  with DOA separation  $\Delta\theta = 5^\circ, 30^\circ$ .

It can be seen in Fig. 13 that as  $N$  (or equivalently  $M_t$ ) increases, the relative recovery error corresponding to  $\mathbf{Z}_q$  and  $\mathbf{Z}_q^{MF}$  decreases proportionally to the reciprocal of the observed SNR. The relative recovery error under scheme I drops faster than under scheme II for both  $M_r = 40$  and  $M_r = 80$  cases. This indicates that scheme I has a better performance than scheme II for the same number of samples.

## V. CONCLUSIONS

We have proposed MIMO-MC radars, which is a novel MIMO radar approach for high-resolution target parameter estimation that involves small amounts of data. Each receive antenna either performs matched filtering with a small number of dictionary waveforms (scheme I) or obtains sub-Nyquist samples of the received signal (scheme II) and forwards the results to a fusion center. Based on the samples forwarded by all receive nodes, and with knowledge of the sampling scheme, the fusion center applies MC techniques to estimate the full matrix, which is then used in the context of existing array-processing techniques, such as MUSIC, to obtain target information. Although ULAs have been considered, the proposed ideas can be generalized to arbitrary configurations. MIMO-MC radars are best suited for sensor networks with large numbers of nodes. Unlike MIMO-CS radars, there is no need for target space discretization, which avoids basis mismatch issues. It has been confirmed with simulations that the coherence of the data matrix at the fusion center meets the conditions for MC techniques to be applicable. The coherence of the matrix is always bounded by a small number. For scheme I, that number approaches 1 as the number of transmit and receive antennas increases and as the targets separation increases. For scheme II, the coherence does not depend as much on the number of transmit and receive antennas, or the target separation, but it does depend on  $N$ , the number of Nyquist samples within

one pulse, which is related to the bandwidth of the signal, i.e., the coherence increases as  $N$  increases. Comparing the two sampling schemes, scheme I has better performance than scheme II for the same number of forwarded samples.

## APPENDIX. PROOF OF $\mu_0 = \mu_1 = 1$ FOR RANK-1 MATRIX $\mathbf{Z}_q^{MF}$

PROOF Suppose that there are  $K, K \geq 2$  targets in the search space, all with the same DOA, say  $\theta_1$ . The noise-free receive data matrix  $\mathbf{Z}_q^{MF}$  can be written as

$$\begin{aligned} \mathbf{Z}_q^{MF} &= \mathbf{B}\Sigma\mathbf{D}_q\mathbf{A}^T \\ &= [\mathbf{b}(\theta_1), \dots, \mathbf{b}(\theta_1)] \begin{bmatrix} \beta_1 & & \\ & \ddots & \\ & & \beta_K \end{bmatrix} \begin{bmatrix} d_1 \\ \vdots \\ d_K \end{bmatrix} \\ &\quad \times [\mathbf{a}(\theta_1), \dots, \mathbf{a}(\theta_1)]^T \\ &= \left( \sum_{k=1}^K \beta_k d_k \right) \mathbf{b}(\theta_1) \mathbf{a}^T(\theta_1), \end{aligned} \quad (20)$$

where  $d_k$  is the Doppler shift of the  $k$ th target. Its compact SVD is

$$\mathbf{Z}_q^{MF} = \mathbf{u}\sigma\mathbf{v}^H, \quad (21)$$

where  $\mathbf{u}^H\mathbf{u} = 1, \mathbf{v}^H\mathbf{v} = 1$ , and  $\sigma$  is the singular value.

By applying the QR decomposition to the receive-steering vector  $\mathbf{b}(\theta_1)$ , we have  $\mathbf{b}(\theta_1) = \mathbf{q}_r r_r$ , where  $\mathbf{q}_r^H \mathbf{q}_r = 1$  and  $r_r = \sqrt{M_r}$ . The expression of  $\mathbf{q}_r$  is given by

$$\mathbf{q}_r = \frac{1}{\sqrt{M_r}} \left[ 1, e^{j\frac{2\pi}{\lambda} d_r \sin(\theta_1)}, \dots, e^{j\frac{2\pi}{\lambda} (M_r-1) d_r \sin(\theta_1)} \right]^T. \quad (22)$$

Similarly, applying the QR decomposition to the transmit steering vector  $\mathbf{a}(\theta_1)$ , we have  $\mathbf{a}(\theta_1) = \mathbf{q}_t r_t$ , where  $\mathbf{q}_t^H \mathbf{q}_t = 1$  and  $r_t = \sqrt{M_t}$ . The expression of  $\mathbf{q}_t$  is given by

$$\mathbf{q}_t = \frac{1}{\sqrt{M_t}} \left[ 1, e^{j\frac{2\pi}{\lambda} d_t \sin(\theta_1)}, \dots, e^{j\frac{2\pi}{\lambda} (M_t-1) d_t \sin(\theta_1)} \right]^T. \quad (23)$$

Therefore, it holds that

$$\mathbf{Z}_q^{MF} = \mathbf{q}_r r_r \underbrace{\left( \sum_{k=1}^K \beta_k d_k \right)}_{\eta} r_t \mathbf{q}_t^T, \quad (24)$$

where  $\eta$  is a complex number. Its SVD can be written as  $\eta = q_1 \rho q_2^*$ , where  $|q_1| = |q_2| = 1$ , and  $\rho$  is a real number. Thus,

$$\mathbf{Z}_q^{MF} = \mathbf{q}_r q_1 \rho q_2^* \mathbf{q}_t^T = \mathbf{q}_r q_1 \rho (\mathbf{q}_t^* q_2)^H, \quad (25)$$

where  $(\mathbf{q}_r q_1)^H \mathbf{q}_r q_1 = |q_1|^2 \mathbf{q}_r^H \mathbf{q}_r = 1$  and  $(\mathbf{q}_t^* q_2)^H \mathbf{q}_t^* q_2 = |q_2|^2 (\mathbf{q}_t^H \mathbf{q}_t)^* = 1$ . By the uniqueness of the singular value, it holds that  $\rho = \sigma$ . Therefore, we can set  $\mathbf{u} = \mathbf{q}_r q_1$  and  $\mathbf{v} = \mathbf{q}_t^* q_2$ .

Let  $\mathbf{q}_r^{(i)}$  denote the  $i$ th element of vector  $\mathbf{q}_r$ . The coherence  $\mu(U)$  is given by

$$\begin{aligned}\mu(U) &= \frac{M_r}{1} \sup_{i \in \mathbb{N}_{M_r}^+} \|\mathbf{q}_r^{(i)}\|_2^2 \\ &= M_r \sup_{i \in \mathbb{N}_{M_r}^+} \|\mathbf{q}_r^{(i)}\|_2^2 \\ &= 1.\end{aligned}\quad (26)$$

Let  $\mathbf{q}_t^{*(i)}$  denote the  $i$ th element of vector  $\mathbf{q}_t^*$ . The coherence  $\mu(V)$  is given by

$$\begin{aligned}\mu(V) &= \frac{M_t}{1} \sup_{i \in \mathbb{N}_{M_t}^+} \|\mathbf{q}_t^{*(i)}\|_2^2 \\ &= M_t \sup_{i \in \mathbb{N}_{M_t}^+} \|\mathbf{q}_t^{*(i)}\|_2^2 \\ &= 1.\end{aligned}\quad (27)$$

Consequently, we have  $\mu_0 = \max(\mu(U), \mu(V)) = 1$ . In addition, we have  $\mu_1 \leq \mu_0 \sqrt{K} = 1$  [10]. It always holds that  $\mu_1 \geq 1$ . Thus,  $\mu_1 = 1$ . Therefore, we have  $\mu_0 = \mu_1 = 1$ .

**Shunqiao Sun** received the B.E. degree in electrical information engineering from Southern Yangtze University, Wuxi, China, in 2004, the M.S. degree in communication and information systems from Fudan University, Shanghai, China, in 2011. Since September 2011, he has been working toward the Ph.D. degree at the Department of Electrical and Computer Engineering, Rutgers, The State University of New Jersey. He was Hardware Engineer II of Kinpo Electronics from July 2004 to August 2008, focusing on embedded systems design. His research interests are digital signal processing in the area of wireless communications and radar systems, including cognitive radio networks, compressive sensing, and matrix completion-based MIMO radar.

**Waheed U. Bajwa** received B.E. (with Honors) degree in electrical engineering from the National University of Sciences and Technology, Pakistan, in 2001, and M.S. and Ph.D. degrees in electrical engineering from the University of Wisconsin-Madison in 2005 and 2009, respectively. He was a postdoctoral research associate in the Program in Applied and Computational Mathematics at Princeton University from 2009 to 2010, and a research scientist in the Department of Electrical and Computer Engineering at Duke University from 2010 to 2011. He is currently an assistant professor in the Department of Electrical and Computer Engineering at Rutgers University. His research interests include high-dimensional inference and inverse problems, sampling theory, statistical signal processing, computational harmonic analysis, machine learning, wireless communications, and applications in biological sciences, complex networked systems, and radar and image processing.

Dr. Bajwa has more than three years of industry experience, including a summer position at GE Global Research, Niskayuna, NY. He received the Best in Academics Gold Medal and President's Gold Medal in Electrical Engineering from the National University of Sciences and Technology (NUST) in 2001, the Morgridge Distinguished Graduate Fellowship from the University of Wisconsin-Madison in 2003, the Army Research Office Young Investigator Award in 2014, and the National Science Foundation CAREER Award in 2015. He coedited a special issue of Elsevier Physical Communication Journal on Compressive Sensing in Communications (2012), coorganized 1st CPS Week Workshop on Signal Processing Advances in Sensor Networks (2013), and cochaired IEEE GlobalSIP Symposium on New Sensing and Statistical Inference Methods (2013). He is currently an associate editor of the IEEE Signal Processing Letters and a senior member of the IEEE.

**Athina P. Petropulu** received her undergraduate degree from the National Technical University of Athens, Greece, and the M.Sc. and Ph.D. degrees from Northeastern University, Boston MA, all in electrical and computer engineering. Between 1992–2010, she was faculty at the Department of Electrical and Computer Engineering at Drexel University. Since 2010, she is professor and chair of the Electrical and Computer Engineering Department at Rutgers, The State University of New Jersey. She has held visiting appointments at SUPELEC in France and at Princeton University. Dr. Petropulu’s research interests span the area of statistical signal processing with applications in wireless communications, networking, and radar systems. She is recipient of the 1995 Presidential Faculty Fellow Award in Electrical Engineering given by NSF and the White House. She is the coauthor (with C. L. Nikias) of the textbook entitled, “Higher-Order Spectra Analysis: A Nonlinear Signal Processing Framework,” (Englewood Cliffs, NJ: Prentice-Hall, Inc., 1993).

Dr. Petropulu is a fellow of IEEE. She has served as editor-in-chief of the IEEE Transactions on Signal Processing (2009–2011), IEEE Signal Processing Society Vice President-Conferences (2006–2008), and member-at-large of the IEEE Signal Processing Board of Governors. She was the general chair of the 2005 International Conference on Acoustics Speech and Signal Processing (ICASSP-05), Philadelphia, PA. She is corecipient of the 2005 IEEE Signal Processing Magazine Best Paper Award and the 2012 Meritorious Service Award from the IEEE Signal Processing Society.
